Epileptic spasms are a feature of DEPDC5 mTORopathy

ABSTRACT

Objective: To assess the presence of DEPDC5 mutations in a cohort of patients with epileptic spasms.

Methods: We performed DEPDC5 resequencing in 130 patients with spasms, segregation analysis of variants of interest, and detailed clinical assessment of patients with possibly and likely pathogenic variants.

Results: We identified 3 patients with variants in DEPDC5 in the cohort of 130 patients with spasms. We also describe 3 additional patients with DEPDC5 alterations and epileptic spasms: 2 from a previously described family and a third ascertained by clinical testing. Overall, we describe 6 patients from 5 families with spasms and DEPDC5 variants; 2 arose de novo and 3 were familial. Two individuals had focal cortical dysplasia. Clinical outcome was highly variable.

Conclusions: While recent molecular findings in epileptic spasms emphasize the contribution of de novo mutations, we highlight the relevance of inherited mutations in the setting of a family history of focal epilepsies. We also illustrate the utility of clinical diagnostic testing and detailed phenotypic evaluation in characterizing the constellation of phenotypes associated with DEPDC5 alterations. We expand this phenotypic spectrum to include epileptic spasms, aligning DEPDC5 epilepsies more with the recognized features of other mTORopathies. Neurology Genet 2015;1:e17; doi: 10.1212/NXG.0000000000000016

GLOSSARY

ExAC = Exome Aggregation Consortium; FCD = focal cortical dysplasia; FFEVF = familial focal epilepsy with variable foci; MAF = minor allele frequency; mTOR = mammalian target of rapamycin; TSC = tuberous sclerosis complex.

Autosomal dominant mutations in DEPDC5 cause familial focal epilepsy with variable foci (FFEVF). 1,2 FFEVF is characterized by seizures arising from different cortical regions in different family members, and onset ranges from infancy to adulthood. 1,3–7 Clinical presentation is highly variable and reduced penetrance of ~66% is usual. 1,2 Families may show patterns that are effectively subsets of FFEVF, such as a phenotypically homogeneous pattern of autosomal dominant nocturnal frontal lobe epilepsy; individuals with rolandic epilepsy have also been described. 1,2,8–10 Recently, DEPDC5 mutations were reported in patients with various brain malformations, challenging the long-held distinction between lesional and nonlesional epilepsies. 11–13

DEPDC5 forms part of the GATOR1 complex, a negative regulator of the mammalian target of rapamycin (mTOR) pathway. 14 Mutations in other mTOR pathway proteins TSC1 and

Continued
Infantile spasms are part of the clinical triad of epileptic spasms, hypsarrhythmia, and developmental arrest or regression that forms the infantile spasms syndrome or West syndrome. While epileptic spasms typically begin in infancy at around 6 months, later onset may occur. The etiology of infantile spasms is an important determinant of developmental outcome but is unknown in one-third of cases. Given that spasms are a frequent feature in TSC and we observed spasms in 1 family in our initial report of DEPDC5 in FFEVF, we systematically searched for DEPDC5 variation in 130 patients with epileptic spasms.

**METHODS** Standard protocol approvals, registrations, and patient consents. Patients were recruited from the epilepsy clinic at Austin Health, from the practices of investigators, and by referral for epilepsy genetics research from around Australia and internationally. Electroclinical phenotyping was performed as previously outlined. In patients with DEPDC5 variants, brain MRI was systematically reviewed by a pediatric neuroradiologist. Informed consent was obtained from the patient or his or her parent or legal guardian. The study was approved by the Institutional Review Boards of Austin Health and The University of Washington.

**RESULTS** Molecular analysis. We sequenced all DEPDC5 cases, identified through commercial genetic testing (D3H11), and additional phenotypic data on cousins from our earlier report (family E). We considered only nonsynonymous, splice site, or frameshift variants that were present at an allele frequency <1% in ~61,000 exomes of the Exome Aggregation Consortium (ExAC) data set (to exclude single nucleotide polymorphisms) for further analysis and performed segregation analysis for these rare variants in available family members. We considered truncating variants to be pathogenic and missense variants that were either inherited from an affected parent or arose de novo to be possibly pathogenic. Maternity/paternity was confirmed using the PowerPlex S5 system (Promega, Madison, WI). We included an additional novel DEPDC5 case, identified through commercial genetic testing (D3H11), and additional phenotypic data on cousins from our earlier report (family E). Given that spasms are a frequent feature in TSC and we observed spasms in 1 family in our initial report of DEPDC5 in FFEVF, we systematically searched for DEPDC5 variation in 130 patients with epileptic spasms.
A total of 92 of 130 patients had West syndrome, while 38 had epileptic spasms in association with other epileptic encephalopathies. In 2 cases (families A and C), the DEPDC5 variants occurred de novo. Patient A:III:2 had a truncating mutation not present in controls. Patient B:III:2 inherited a truncating mutation not seen in controls from a father with frontal lobe epilepsy. Patient C:III:3, who was of Chinese descent, had a de novo missense variant that disrupted a highly conserved nucleotide, which was predicted to be damaging by 2 of 3 in silico tools (table 1). This variant occurred in 71 individuals in ExAC, including 66 of 8,732 individuals of East Asian descent (minor allele frequency [MAF] 0.7%).

We describe 2 additional families with inherited DEPDC5 variants in whom 1 or more affected family members presented with spasms (table 1, figure 1). Family D, ascertained through commercial testing, had a Tyr281Phe variant, which is highly conserved and predicted to be damaging by 2 of 3 tools (table 1). This variant was present in 5 of 67,552 (MAF 0.0007%) individuals of non-Finnish European descent. Family E carries a splice site mutation, and we describe 2 patients with infantile spasms from this previously reported family.1

Clinical characterization. Spasms were the presenting seizure type in each case, with onset at 6–12 weeks in 5 cases and late onset at 2 years, 8 months in 1. Two had easily controlled spasms, both with offset at 6 months. In 4 cases, spasms had focal electroclinical features. EEG features included multifocal epileptiform abnormalities, generalized paroxysmal fast activity,

We describe 6 patients in 5 families with DEPDC5 variants and spasms. Variants arose de novo in 2 cases (families A and C) and were inherited in 3 (families B, D, and E).

---

We describe 6 patients in 5 families with DEPDC5 variants and spasms. Variants arose de novo in 2 cases (families A and C) and were inherited in 3 (families B, D, and E).
Hypsarrhythmia was seen in 1 patient. Three cases had later focal seizures with impaired awareness and onset from 9 months to 13 years; all were refractory. Atypical absence seizures beginning at age 11 occurred in C:III:3. One patient, E:IV:2, had normal intellect and no developmental regression with spasm onset; at 34 years, she was a professional. Three patients showed regression with seizure onset and 1 was never normal. Patient C:III:3 showed an additional later decline at age 15 years. Three had autistic features.

Brain MRI revealed temporal focal cortical dysplasia (FCD) in A:III:2 and frontal FCD in D:II:1 (figure e-2). MRI was normal in 3 cases and not performed in 1. Epilepsy surgery was performed in 2 cases. D:II:1 had a histologically confirmed left frontal FCD type IIA (figure e-3). After anatomic left frontal lobectomy, the patient was seizure-free for 6 months and then had return of head drops and tonic seizures. Repeat surgery with a functional left hemispherectomy resulted in seizure freedom for 2.5 years. She now has monthly staring spells. Left lateral temporal corticectomy in C:III:3 was unsuccessful; pathology was normal.

**DISCUSSION** We first identified **DEPDC5** in familial focal epilepsy, and here we show its relevance to epileptic spasms, illustrating the convergence of phenotypes in genetic mutations of the mTOR pathway.

Our findings suggest that greater significance should be attributed to a family history of focal seizures in patients with epileptic spasms. Affected family members had focal epilepsies emanating from different cortical regions, consistent with the pattern of FFEVF. Infantile spasms have an identifiable etiology in ~60% cases and may include hypoxic-ischemic or metabolic encephalopathies, malformations, infection, and chromosomal anomalies. A family history of spasms is rare but has been described in conditions such as TSC and specific genetic diseases such as **ARX**. The importance of de novo mutations has recently been emphasized, with a pathogenic mutation attributed to a single gene identified in 5%–16% of cases (n = 268 from 3 studies using next-generation sequencing technologies) (table e-1). The most frequently mutated genes were **STXBP1** (n = 6), **CDKL5** (n = 2), **KCNQ2** (n = 2), and **ALG13** (n = 2). Our finding of a **DEPDC5** variant in up to 2.3% of patients in our cohort suggests that this gene may be one of the more frequent genes associated with epileptic spasms, taking into account that this cohort may have some fundamental differences from other studies of infantile spasms in which hypsarrhythmia is essential for inclusion.

We identified 3 truncating mutations: 1 occurred de novo and the remaining 2 were inherited. This is...
in keeping with previous reports in which the overwhelming majority of pathogenic \textit{DEPDC5} mutations resulted in premature truncation of the protein (figure 2), suggesting that \textit{DEPDC5} mutations cause disease by haploinsufficiency of the protein. This is further supported by the presence of only 15 truncating variants in the \textasciitilde 61,000 exomes in ExAC. However, we report 2 missense variants, Pro1031His (MAF 0.7%) and Tyr281Phe (MAF 0.007%), and there are more than 400 missense variants in ExAC. Tyr281Phe is exceedingly rare, and incomplete penetrance of \textit{DEPDC5} mutations may explain the presence of these variants in the population. However, the 0.7% MAF of Pro1031His (arose de novo in family C) seems too high in this population to be explained solely by incomplete penetrance, and this result needs to be interpreted with caution. This may also be true for several reported missense mutations also present in controls at low frequencies (figure 2).\textsuperscript{1,4} It will be important to develop robust functional experiments to assess the pathogenicity of these missense variants in the future.

We have combined a targeted resequencing approach in 130 patients and results from clinical diagnostics and extended phenotyping in a known mutation-positive family to determine several notable features that highlight the variability of onset and outcome of \textit{DEPDC5}-associated spasms. Our findings expand the \textit{DEPDC5} phenotypic spectrum to include more severe epilepsies presenting with spasms. First, the outcome may be excellent with normal intellect, although most of our patients had intellectual disability with or without autistic features. Second, seizures were controlled with monotherapy in 2 patients. Third, 1 patient had later onset of spasms in the third year with further cognitive decline in adolescence. Fourth, 2 patients had malformations with FCD; in 1, surgery resulted in seizure improvement. Our findings show that \textit{DEPDC5} variants are associated with FCD type IIA. Surprisingly, only 1 patient showed hypsarrhythmia on EEG; however, all had highly abnormal EEGs with abundant epileptiform activity, which can be associated with epileptic spasms. The absence of classic hypsarrhythmia means that these patients differ from those with West syndrome, which has been the focus of many recent genomic studies.

Of note, spasms were present in patients with FCD (2 patients) and those without FCD (3 patients) after careful scrutiny of the MRI. Because many patients with focal epilepsies and \textit{DEPDC5} mutations have normal MRI,\textsuperscript{1,11,12} the presence of detectable lesions is not necessary for the development of seizures. Rather, loss-of-function mutations in \textit{DEPDC5}, an inhibitor of the mTOR pathway, presumably lead to excessive signaling of this pathway, which has many functions that could conceivably contribute to hyperexcitability. Moreover, exactly how \textit{DEPDC5} mutations lead to a cortical malformation is not known. It has been hypothesized that the presence of a “second hit” is required for the development of these lesions.\textsuperscript{11} This scenario would be analogous to TSC, in which a second mutation in the mTOR regulators \textit{TSC1} and \textit{TSC2} is reported in some tumors of patients with TSC.\textsuperscript{22} In patients with \textit{DEPDC5} mutations, this “second hit” could occur either on the other allele or on another gene involved in the mTOR pathway. Alternatively, an acquired cause, such as a human papillomavirus, has been conjectured to be a “second hit” in FCD.\textsuperscript{23} In the future, deep targeted or even whole-exome sequencing should be performed on resected tissue to explore this hypothesis.

Given the incomplete penetrance of \textit{DEPDC5} mutations and the discovery of both inherited and de novo mutations, molecular approaches for epileptic spasms should interrogate both inheritance patterns. The detection of inherited mutations has important reproductive counseling implications for families of children with spasms, which needs to incorporate increased risk for comorbidities such as intellectual disability and autism spectrum disorders. The recognition of spasms in \textit{DEPDC5} epilepsies parallels other mTORopathies such as TSC and STE20-related kinase adaptor alpha syndrome.\textsuperscript{24} Although many \textit{DEPDC5} epilepsies are milder, the convergence of the phenotypic spectrum and molecular pathways suggests that targeted mTOR therapies may benefit patients with the more severe \textit{DEPDC5} disorders.\textsuperscript{24}
