Abstract

Objective

We clinically and molecularly characterize a new family with autosomal dominant rimmed vacuolar myopathy (RVM) caused by mutations in the *HSPB8* gene.

Methods

We performed whole-exome and whole-genome sequencing in the family. Western blot and immunocytochemistry were used to analyze 3 patient fibroblasts, and findings were compared with their age- and sex-matched controls.

Results

Affected patients have distal and proximal myopathy, with muscle biopsy showing rimmed vacuoles, muscle fiber atrophy, and endomysial fibrosis typical of RVM. Muscle MRI showed severe relatively symmetric multifocal fatty degenerative changes of the lower extremities. We identified a duplication of C at position 515 of the *HSPB8* gene (c.515dupC) by whole-genome sequencing, which caused a frameshift with a predicted alternate stop codon p.P173SFS*43 in all affected individuals, resulting in an elongated protein product. Western blot and immunocytochemistry studies revealed reduced expression of heat shock protein beta 8 in patient fibroblasts compared with control fibroblasts, in addition to disrupted autophagy pathology.

Conclusions

We report a novel family with autosomal dominant RVM caused by the c.515dupC mutation of the *HSPB8* gene, causing a translational frameshift that results in an elongated protein. Understanding the mechanism for the RVM pathology caused by mutated chaperone will permit novel targeted strategies to alter the natural history progression. As next-generation sequencing becomes more available, additional myopathic families will be identified with *HSPB8* mutations.

Glossary

CASA = chaperone-assisted selective autophagy; **CMT** = Charcot-Marie-Tooth; **FLNC** = filamin C; **HSPB** = heat shock protein beta; **MRI** = Medical Research Council; **NCS** = nerve conduction study; **RVM** = rimmed vacuolar myopathy.

Heat shock protein beta 8 (HSPB8), also known as heat shock protein 22, is involved in chaperone-assisted selective autophagy (CASA) in cells.¹ CASA is a process that maintains muscle cytoskeleton by facilitating the degradation of damaged components. Disruption of genes in the chaperone-assisted degradation pathway is implicated in several myopathies. CASA interacts with filamin C (FLNC), a flexible actin cross-linker that is present within muscle Z-disks² and along cytoskeleton-associated integrin where it functions to anchor actin during mechanical stress.³ DnaJ Heat Shock Protein Family (Hsp40) Member B6 (DNAJB6) thought to be the first protein that interacts with Heat Shock Protein Family A (Hsp70) Member 8 (HSPA8)⁴ then complexes with HSPB8. BCL2 Associated Athanogene 3 (BAG3) is a coupling factor that mediates HSPA8 and HSPB8 interaction.¹ Mutations of several CASA-associated proteins are known to be associated with myopathies: DNAJB6 is associated with limb-girdle muscular dystrophy 1D,⁵ BAG3,^{6,7} and FLNC with skeletal and cardiac myopathies.^{8,9}

Previous studies associated *HSPB8* mutations with Charcot-Marie-Tooth (CMT) type 2L^{10,11} and distal hereditary motor neuropathy type IIa.¹² It was only after an exome analysis that the association with distal myofibrillar and rimmed vacuolar neuromyopathy was established,¹³ identifying a heterozygous change in *HSPB8* in 2 families: c.421A>G; p.K141E in family 1 and the c.515 insC p.P173SfsX43 in family 2. Affected patients had a distal neuromyopathy that showed myofibrillar aggregates and rimmed vacuoles combined with a clear neurogenic component on biopsy and EMG studies. Recently, a c.508_509delCA mutation was identified, predicted to produce a frameshift mutation leading to alteration of the last 27 amino acids and elongation of the polypeptide by 17 residues in 3 families.¹⁴ Finally, a family was identified with c.421A>G p.K141E *HSPB8* mutations manifesting with pes cavus, hammer toes, and muscle atrophy with biopsy findings including rimmed vacuoles and myopathic changes.¹⁵ Here, we describe a new family with an *HSPB8* p.Pro173fs mutation manifesting as rimmed vacuolar myopathy (RVM).

Methods

Standard protocol approvals, registrations, and patient consents

This study was approved by the University of California Irvine Institutional Review Board (#2009-1005). All subjects provided approved consent for the studies. The study is also listed in ClinicalTrials.gov (Identifier: NCT01353430).

Molecular studies

Extensive gene panel of the genes involved in neuromuscular diseases performed by EGL Genetics Diagnostic Laboratory

at Emory University was negative for the following 35 genes: *ANOS*, *CAPN3*, *CAV3*, *COL6A1*, *COL6A2*, *COL6A3*, *DAG1*, *DES*, *DMD*, *DYSF*, *EMO*, *FHL1*, *FKRP*, *FKTN*, *FLNC*, *GAA*, *GNE*, *ISPD*, *LMNA*, *MYOT*, *PLEC*, *POMGNT1*, *POMT1*, *POMT2*, *SGCA*, *SGCB*, *SGCD*, *SGCG*, *SMCHD1*, *SYNE1*, *SYNE2*, *TCAP*, *TRIM32*, *TTN*, and *VCP*.

Whole-exome sequencing and segregation analysis was performed by Ambry Genetics.¹⁶ Briefly, the sample was prepared using the IDT xGen Exome Research Panel V1.0 (Integrated DNA Technologies), sequenced using the Illumina HiSeq4000 sequencer (Illumina, San Diego, CA). Data processing and interpretation were performed as previously described.¹⁶

Subsequent genome sequencing was performed by OtagoGenetics Corporation (Atlanta, GA) and the data analyzed by Variantyx, Inc. (Framingham, MA). For sequencing, libraries were generated using the Truseq Nano DNA Library Sample preparation Kit and sequenced on the Illumina HiSeq X Ten system (Illumina, USA) to achieve average read depth of about 30X. Variants were detected, annotated, analyzed, and reported using the Genomic Intelligence platform (version 1/.13.2.0) integrating the knowledge in a variety of databases and tools (Variantyx Inc). Sanger sequencing was used to confirm the *HSPB8* variant in the proband and for segregation studies in his family.

HSPB8 protein study and autophagic activity of mutant HSPB8

Because of the unavailability of patient myoblasts, we studied patient fibroblasts from the proband, his mother, and maternal uncle derived from skin biopsy samples (P1: 64-001, P2: 64-002, P3: 64-005). Fibroblasts of the 3 age- and sex-matched healthy controls from Coriell Repository (C1: GM22246, C2: AG12786, C3: AM03529A) were used to test the *HSPB8* expression level for comparison. Western blotting and immunocytochemistry studies using *HSPB8* antibody (Millipore Sigma HPA015876) were performed as previously described.¹⁷ We also monitored the autophagic activity of mutant *HSPB8*¹⁸ using autophagosomal markers LC3B (Abcam, ab48394), P62/SQSTM1 (ab56416), and BAG3 (ab47124) antibodies.

HSPB8 protein expression under heat shock conditions

Under stress conditions such as heat shock, the concentration of small heat shock proteins such as *HSPB8* would be expected to increase to perform their chaperone activity of binding to misfolded proteins and blocking the formation of aggregates.^{19,20} The heat shock experiment was performed as

follows: fibroblasts were seeded on chambered slides (Ibidi, IbiTreat 80826) in subconfluent density for 24 hours. The slides were sealed with parafilm, placed in an aluminum foil box, and immersed in 43°C water bath for 30 minutes. Unheated control slides were also sealed for 30 minutes but kept in an incubator (37°C). Then, all slides were unsealed, and their recovery was followed for 24 hours in the incubator before immunocytochemistry was performed.^{19,20}

Data availability

All the data from this study will be made available.

Results

Clinical studies

Case 1

The proband (IV:8) is a 44-year-old man born to non-consanguineous Northern European parents of French ancestry with a family history of autosomal dominant inheritance of muscle weakness in his mother and his maternal uncle (figure 1). He was an all-state athlete in his 20s. He had persistent elevated liver enzymes from age 28 years and first noticed lower limb weakness in the mid-30s with progressive bilateral foot drop and occasional falls. At age 35 years, he developed foot pain and ankle dorsiflexion weakness for which he wore ankle foot orthoses. At age 42 years, he noticed difficulty raising his arms above his head, and at age 43 years, difficulty rising from a chair and climbing stairs.

On physical examination, there was mild scapular winging (figure 2), diffuse muscle weakness noted predominantly in the lower extremities, and no sensory loss. He had a wide steppage gait related to his bilateral foot drop, was unable to tandem walk or walk on his heels or toes, and had a lumbar

lordosis. The Medical Research Council (MRC) scale score of his foot dorsiflexors was 2/5, and that of the extensor hallucis longus was 1/5 on the right and 2/5 on the left. The MRC scale score of the infraspinatus, deltoid, finger extensors, hip flexors, hip extensors, knee flexors, hip adductors, and hip abductors was 4/5. Reflexes were diminished 1/4 bilaterally of the biceps, triceps, brachioradialis, knee, and absent at the ankle. T1-weighted MRI showed severe relatively symmetric multifocal fatty degenerative changes of the lower extremities, preferentially affecting the vastus medialis and intermedius, adductor magnus and semitendinosus at the thigh level, and predominantly anterior and lateral compartments more than calf muscle of the lower legs (figure 2, B and C). Laboratory studies revealed normal comprehensive metabolic profile, normal alkaline phosphatase 28 U/L, and elevated total cholesterol 237 mg/dL (normal < 150 mg/dL). His medical history included asymptomatic right bundle branch block, pseudogout, benign prostatic hyperplasia, and rosacea. Although he was asymptomatic, pulmonary function studies revealed respiratory insufficiency with decreased Forced Vital Capacity (sitting) of 4 L (43% of predicted). His maximum inspiratory pressure was -72 cm H₂O. BiPAP was recommended for his respiratory insufficiency. The patient is taking nonprescribed nutritional supplements.

Case 2

The proband's mother (III:14) aged 64 years first presented with difficulty raising her arms and weakness in her legs and feet not until age 56 years. She then progressed to having difficulty walking up stairs at age 59 years and developed difficulty walking on flat ground and weakness in her hands at age 60 years. Her medical history included hyperuricemia, hypertension, and type 2 diabetes mellitus and tendon surgery of her right thumb.

Figure 1 Family pedigree showing autosomal dominant inheritance

The filled upper right quadrant indicates myopathy, and the filled upper left quadrant indicates nonspecific neurologic symptoms. The arrow indicates the proband.

Figure 2 Muscular involvement of the HSPB8 disease

(A) Photograph of the proband showing scapular winging and bilateral wasting of deltoids. (B) T1-weighted MRI of the proband showing severe relatively symmetric multifocal fatty degenerative changes of bilateral lower extremities and (C) proximal lower extremities preferentially affecting the vastus medialis and intermedius together with the adductor magnus and semitendinosus on the thigh level, as well as predominately anterior and lateral compartments more than soleus muscle of the distal legs.

Physical examination revealed mild distal extremity weakness and diminished 1/4 reflexes bilaterally of her biceps, triceps, brachioradialis, and patella. Her Achilles tendon reflex was absent. She had a wide based and unbalanced gait with a lordotic posture. There was no scapular winging, pes cavus, skeletal dysplasia, respiratory distress, signs of cranial nerve involvement, or sensory loss. CT of the lung revealed right basilar consolidative infiltrate vs atelectasis at the left lung base.

Muscle biopsy of her left vastus lateralis revealed adipose tissue infiltration, moderate to severe endomysial fibrosis,

muscle fiber size variation, numerous atrophic muscle fibers, increase of internalized nuclei, and rimmed vacuoles. There were no necrotic fibers, regenerating muscle fibers, or evidence of inflammation (figure 3). No medications were prescribed for this patient.

Case 3

The proband's maternal uncle (III:15) is a 66-year-old man who first became aware of a steppage gait at 42 years and weakness of his great toe and right hand at age 44 years. This progressed to using a cane and difficulty going up stairs at age 46–47 years. At age 52 years, he started swimming instead of running for exercise and starting to use Canadian crutches. At age 59 years, he started using a manual wheelchair, and at age 64 years, he transitioned to a power wheelchair. At age 61 years, he has noticed that his breathing became more difficult.

His medical history includes neurogenic bladder, mild obstructive sleep apnea, gout and hearing loss of his right ear, and 20 incidences of recurrences of basal cell nevi and squamous cell carcinoma of the skin.

On physical examination, there was no pes cavus, skeletal dysplasia, camptocormia, scapular winging, or signs of cranial nerve or cerebellar involvement. He had reduced sensation to light touch below knees bilaterally, and muscle strength examination revealed distal > proximal weakness. The MRC scales were neck flexion 4–/5, neck extension 4/5, shoulder abduction 4–/5, elbow flexion 4–/5 and extension 3+/5, finger abduction 5–/5, hip flexion 2/5 and extension 3+/5, knee flexion 3+/5 and extension 2/5, ankle dorsiflexion 1/5, and plantarflexion 3–/5. EMG and nerve conduction studies (NCSs) revealed abnormal findings suggestive of a myopathic pattern primarily in distal musculature with evidence of a motor neuropathy.

Chest x-ray revealed low lung volumes without evidence of cardiovascular disease. Pulmonary function tests revealed restrictive lung disease with poor lung capacity with a forced vital capacity of 43%, and BiPAP was recommended. Cardiac CT showed an elevated coronary calcium score of 244 but no cardiomyopathy.

Body CT revealed atrophy and fatty infiltration of his psoas muscle, benign prostatic hyperplasia, atelectasis with prominent interstitial markings of his lung bases bilaterally, renal cyst, gallstone, and a calcified granuloma in his liver. No medications were prescribed for this patient.

Family history of other relatives

Family history was significant for the proband's maternal grandfather losing his ability to walk at age 38 years and for developing cardiac problems in his fifties. On review of the extended family, his grandfather's brother lost his ability to walk at age 35 years, and the great grandmother lost her ability to walk at age 56 years. Five other family members reported nonspecific neurologic symptoms; however, these individuals tested negative for the familial mutation. Figure 4 depicts the pedigree with *HSPB8* mutation status indicated with a “+.”

Figure 3 Muscle biopsy shows rimmed vacuoles

(A) Muscle histology of a biopsy of the left vastus lateralis from case 2 shows the presence of rimmed vacuoles (in 3 fibers), adipose replacement, moderate to severe endomysial fibrosis, muscle fiber size variation, numerous atrophic muscle fibers, and increase in central nuclei. (B) Semithin section stained with toluidine blue showing a single fiber with accumulated autophagic vacuoles, corresponding to rimmed vacuolar changes in muscle cryosections.

Molecular studies

Extensive neuromuscular 35-gene panel testing was negative in the proband and uncle notably for facioscapulohumeral muscular dystrophy, *GNE* and *VCP* associated hereditary

inclusion body myopathy. Full exome sequencing and genotype-phenotype correlation based on exome data analysis revealed notable alterations in *CCDC78*, *HSPB8*, *MUSK*, *MYH14*, *TRIM32*, and *TTN*—none of which was

Figure 4 Sequencing of the *HSPB8* gene

(A) Chromatogram from the proband revealing the frameshift mutation c.515dupC p.Pro173fs, which was similarly identified in all affected individuals. (B) The mRNA that results from this mutation has 5 splice variants with size ranging from 27 to 244 aa. Only the first 3 contain an α -crystallin domain and are coding. The red boxes are exons with their size being proportional to their length. The wide colored boxes are introns. Similarly colored introns are identical. The purple introns are upstream open reading frames. The solid black vertical lines indicate validated cap sites at the 5' end, and the dotted black lines indicate validated polyadenylation sites at the 3' end. The clear boxes are untranslated regions. (C) Conservation of the sequence of amino acids within HSPB8 across species reveals a very well conserved protein. (D) The predicted sequence of amino acids in the mutant HSPB8 protein (214 amino acids) is longer than its wild-type counterpart (196 amino acids).

considered contributory based on the known molecular and clinical spectrum of these genes at the time of testing. Subsequent genome sequencing identified a mutation in the *HSPB8* gene identical to the French family 2, which had recently been reported by Ghaoui et al.¹³ after whole-exome analysis.

HSPB8 p.Pro173fs

The *HSPB8* gene mutation identified consists of a duplication of C at position 515, located in coding exon 3 (the last coding exon) causing a translational frameshift with a predicted alternate stop codon (c.515dupC, p.P173Sfs*43). The alteration changes the remaining 25 amino acids of the protein and elongates the protein by a further 18 amino acids (figure 4). This variant is not observed in any of the control population databases including gnomAD. The calculated severity score is 1.0 on a scale of 0.0–1.0. According to Human Gene Mutation Database/ClinVar, the *HSPB8* gene is associated with CMT disease 2L; neuropathy, distal hereditary motor, type II; distal myopathy and motor neuropathy; and distal hereditary motor neuronopathy type 2. Recently, the 515dupC, p.P173Sfs*43 variant had been associated with a progressive distal myopathy and neuropathy in a proband and his brother. Muscle

tissue in the proband showed increased internal nuclei, numerous rimmed vacuolar fibers, splitting, cytoplasmic bodies, and moth-eaten fibers.¹³

HSPB8 and autophagy protein expression in mutant *HSPB8* fibroblasts

Western blot densitometry exhibited up to 50% reduction of *HSPB8* protein expression level in fibroblasts from patients with the *HSPB8* mutation c.515dupC, p.P173Sfs*43 mutation compared with control fibroblasts (figure 5, A and B). The expression of autophagosomal marker LC3B and autophagy receptor p62/SQSTM1 was more pronounced in all patients' fibroblasts in comparison to those from healthy subjects (figure 5).

HSPB8 protein expression under heat shock conditions

As expected, heat shock led to a significant induction of *HSPB8*; however, following the recovery phase, an excessive amount of *HSPB8* protein aggregates was still present in all 3 heated fibroblasts from patients compared with the unheated ones. This phenomenon was not seen in healthy control cells (figure 6).

Figure 5 Expression of *HSPB8*, LC3B, p62/SQSTM1, and BAG3 proteins comparison in patients versus controls

(A) Western blot revealed low *HSPB8*, increased autophagy (LC3, p62) protein expression in patient fibroblasts compared with age- and sex-matched controls. GAPDH was used as a positive loading control. (B) Densitometry analyses of the Western blot results (C) Immunocytochemistry images by confocal microscopy confirmed Western blotting data. Pair 1: patient (P1) and control (C1) fibroblasts; pair 2: P2 and C2; pair 3: P3 and C3.

Discussion

HSPB8 is part of the chaperone-assisted selective autophagy (CASA) complex previously associated with CMT type 2L^{10,11} and distal hereditary motor neuropathy type IIa.¹² Only recently has the new association of hereditary rimmed vacuolar neuromyopathy been described with mutations in the *HSPB8* gene.^{13–15} We report 3 patients from a new family with histologic features of myofibrillar myopathy with aggregates and rimmed vacuoles. The onset of the disease is very similar to the other reported families^{13–15} and manifests as a myopathy before age 50 years affecting the lower extremities more commonly than the upper extremities. The MRI distribution of muscle involvement in our cohort includes muscles of the distal lower extremities similar to previous studies¹³ that described T1-weighted MRI findings of the lower limb muscles and demonstrated diffuse tissue changes early in the disease stage progressing later to fatty replacement typical of a myopathy. In addition, there was a previous report of 5 cases from 2 families and a sporadic case, all with the same *HSPB8* c.508_509delCA (p.Gln170Glyfs*45) mutation predicted to induce a frameshift from amino acid 170 leading to modification of the last 27 amino acids and to 17 additional amino acids.¹⁴ Individuals had bilateral foot drop starting at age 40 years, histology of muscle demonstrated a dystrophic and myofibrillar myopathy pattern, and MRI showed fatty changes in several muscles

including paraspinal muscles and lower limb muscles including the vastus muscles, tibialis anterior, and extensor digitorum longus similar to those reported previously¹³ (table). Most recently, triplets and their mother were reported with distal and proximal muscle weakness, EMG showed mixed myopathic and neurogenic changes, and NCSs showed findings of an axonal neuropathy.¹⁵ Muscle biopsy findings were that of a primary myopathy with rimmed vacuoles in 20% of patients, and MRI revealed fatty degeneration mostly in the quadriceps, adductor magnus, medial gastrocnemius, and peroneus muscles (table).

The family of small heat shock proteins (HSPBs1–10) (22 kDa) represents an important group of ubiquitous proteins involved in several key processes of cellular physiology, such as cell survival, cytoskeletal remodeling, and protein degradation. Aberrant chaperone function is the likely mechanisms for the pathologic protein aggregation seen in *HSPB8* disease. The *HSPB8* c.K141E mutation associated with CMT impairs chaperone activity,²¹ which suggests that the defective or decreased activity is associated with the deteriorating motor neuron function. *HSPB8* expression within motor neurons declines with age,²⁰ which has been hypothesized as the mechanism of the disease presenting in older ages and progressing with age.¹⁸ A contributing factor to the susceptibility of these patients may be impaired formation of neurites in *HSPB8* mutants.²² The *HSPB8* pathology is similar to the

Figure 6 Expression of *HSPB8* protein under heat shock condition

(A) No heat shock condition, (B) heat shock condition. An increase in the amount of *HSPB8* protein was present in 3 heated fibroblasts from patients (B1) compared with nonheated fibroblasts (A1). This phenomenon was not observed in control cells (A2 and B2). Pair 1: patient (P1) and control (C1) fibroblasts; pair 2: P2 and C2; pair 3: P3 and C3.

pathology in myopathies due to gene defects in other components of the CASA complex such as BAG3 and DNAJB6.

Based on results from animal studies, there has been suggestion of a toxic gain-of-function mechanism for *HSPB8* associated CMT.²³ However, our Western blot densitometry studies exhibited a 50% reduction of *HSPB8* protein expression level in patients compared with control fibroblasts (figure 5). Recently, it was noted¹⁴ that N-terminal targeting of the protein did not detect this elongated protein suggesting mRNA decay or protein degradation.²⁴ In addition, *HSPB8* was decreased by 60% by Western blot quantification. The consequences of the effects of the mutant protein are difficult to predict based on current knowledge because *HSPB8* acts in complexes with other chaperones, especially in muscle tissue. The negative effects on the multiprotein complexes may be explained by a dominant negative effect, but haploinsufficiency cannot be excluded. The clear increase of p62 and LC3 in the patient muscle suggests a harmful effect of the mutant protein rather than rapid degradation of the mutant. To clarify this in more detail, a mutant protein-specific antibody would be required to check for eventual accumulation or degradation of the mutant.

Most reported mutations, including the c.515dupC mutation, have occurred within the α -crystallin domain that manifests chaperone activity.²⁵ Previous studies have shown greater binding of these *HSPB8* mutants to the interacting partner *HSPB1*. Expression of mutant *HSPB8* containing the K141C terminal mutations found in hereditary motor and sensory neuropathies in cultured cells had significantly reduced chaperone activity and increased aggregation compared with wild-type protein.¹²

In stress conditions, like heat shock, small heat shock proteins such as *HSPB8* increase in concentration to perform their chaperone activity by binding to misfolded protein and blocking the formation of aggregates. During recovery from heat shock under normal conditions, the transcription factor NF- κ B (Nuclear factor kappa-light-chain-enhancer of activated B cells) activates the removal of misfolded or aggregated proteins by governing the expression of *HSPB8*, thereby increasing cell survival.²⁶ Our studies indicate that patient cells could not recover after the heat shock stress and displayed an increased *HSPB8* expression, also noted by Irobi et al.²⁷

We report a new family with *HSPB8*-associated autosomal dominant RVM, caused by a c.515dupC frameshift mutation resulting in an elongated protein. The clinical features in these individuals bear similarity with recently reported cases. We note reduced expression of *HSPB8* in patient fibroblasts compared with age- and sex-matched control fibroblasts supporting our proposal of haploinsufficiency as the mechanism of disease in this newly described disorder.
