Abstract

Objective
We evaluated whether substrate reduction therapy with miglustat could alter the course of action myoclonus–renal failure syndrome (AMRF), a rare, progressive myoclonic epilepsy with early mortality caused by scavenger receptor class B member 2 (SCARB2) gene mutations.

Methods
We identified an AMRF patient with a biallelic combination of SCARB2 mutations determined by whole exome sequencing. SCARB2 encodes a protein that traffics β-glucocerebrosidase to the lysosomal membrane. Mutations lead to a complex pattern of glucosylceramide accumulation and neurologic symptoms including progressive action myoclonus, seizures, and ataxia. We then evaluated the effect of inhibiting glucosylceramide synthesis, as is used in Gaucher disease. The patient was treated for 3 years with miglustat after several years of steady worsening.

Results
Progression of myoclonus halted, dysphagia resolved, some skills were reacquired, and seizures remained well controlled.

Conclusions
The response suggests that neurologic symptoms of SCARB2-associated AMRF could be ameliorated, at least partly, by targeting glycosphingolipid metabolism with available medications.
Miglustat was started at 100 mg twice daily and increased to designed treatment with a GCS inhibitor (Figure 1C). In trials for neuronopathic Gaucher disease and blood-brain barrier. Venglustat, a CNS-penetrant GCS inhibitor, is therapy, miglustat, is approved for mild type 1 Gaucher disease. (GL1) and its bioactive lipid, glucosylsphingosine.3 Because of its high-penetrance, miglustat is considered an option for Gaucher disease. The GCS synthase (GCS) inhibitors are accepted therapies associated Parkinson disease but was not available (compassionate use declined by the manufacturer). Miglustat exhibits modest CNS penetration and, in addition to Gaucher disease, is approved in Europe for treatment of Niemann-Pick disease type C. Hence, we assessed the response of AMRF to miglustat.

Methods

We conducted a trial in a patient with this rare, devastating disease that has no approved therapy. Whole exome sequencing was performed by array capture and high-throughput sequencing using an Illumina platform. The mean coverage of the exome was >100×, and more than 98% of the exome had at least 20× coverage. SCARB2 variants in the proband were confirmed by Sanger sequencing. Targeted parental sequencing confirmed the inheritance pattern.

To confirm an effect on lysosomal function, leukocyte β-glucocerebrosidase activity was measured. We (P.K.M.) designed treatment with a GCS inhibitor (Figure 1C). Miglustat was started at 100 mg twice daily and increased to 200 mg 3 times a day over 6 months to improve brain delivery. This is the upper end of the dose range that has been used and tolerated in trials for Gaucher disease.4 Myoclonus was evaluated with video recordings and patient reports. Epilepsy, already well controlled via medications, was evaluated by patient seizure reporting and follow-up EEG.

Results

The patient was a 25-year-old lawyer and dancer and presented with seizures and myoclonus. At age 20 years, she developed imbalance and falls with lower extremity jerking. At age 21 years, she developed upper extremity myoclonus and had the first of several bilateral tonic-clonic seizures. At age 22 years, her handwriting started to deteriorate. She developed dysarthria when fatigued. She required a cane at age 23 years and a walker at age 25 years because of lower extremity jerks. Concomitantly, she developed dysphagia. Family history included childhood-onset hearing loss on the maternal side and melanoma on the paternal side, but no seizures or movement disorders (Figure 1A).

Evaluation at age 25 years noted prominent bilateral action myoclonus in her upper more than lower extremities, titubation, wide-based gait, ocular dysmetria, and dysarthria. Mental status, strength, sensation, and reflexes were normal. A video EEG showed sleep-activated, low-amplitude, generalized polyspikes, a myoclonic seizure with a burst of central polyspikes, and innumerable myoclonic jerks without EEG correlates. Brain and spinal MRIs were unrevealing other than mild diffuse atrophy in 2019 compared with that in 2009. Clonazepam had no effect on myoclonus. L-dopa, levetiracetam, and perampanel had mild, transient effects. Valproate had a more sustained effect, but also mild. Clobazam was associated with worsening myoclonus. No medication had a sustained or dramatic response on myoclonus or any effect on progression of other symptoms (Figure 2).

After clinical genetic evaluation, whole exome sequencing revealed 2 pathogenic, biallelic, compound heterozygous
SCARB2 mutations (Figure 1B). One was an insertion of a dinucleotide repeat, *c.431_432insAG* on exon 4 (identical to *c.435_436insAG*), predicted to cause a frameshift and truncate the protein to 160 amino acids (full transcript encodes a 478 amino acid protein). The second, nonsense mutation *c.862C > T* (p.Gln288Ter) on exon 7 was predicted to cause loss of function through protein truncation or nonsense-mediated mRNA decay. Parental analysis confirmed that the mutations were independently inherited (Figure 1B). In homozygous cases, they were previously reported in unrelated individuals with AMRF. No pathogenic *GBA* variants were identified. Acid β-glucosidase activity in peripheral blood leukocytes was 7.5 nmol/h/mg protein, which, while lower than normal (≥ 8.7), was not in diagnostic range for Gaucher disease, where enzyme activity is typically less than 10% of normal value.

With miglustat dose escalation to 200 mg 3 times daily, multiple symptoms were ameliorated (Figure 2). Myoclonus and range of motion improved. The patient remained seizure-free. Dysphagia resolved completely; the patient was even able to eat pieces of steak again. EEG 18 months later showed no epileptiform discharges. Coordination and function improved modestly; for example, she was again able to use a joystick to play video games and to use the TV remote. There were no definite side effects.
Although overall improvements were modest, the previously relentless neurologic progression stopped completely.

Renal function was normal with serum creatinine of 0.9 mg/dL at the time of genetic diagnosis. One year later, she developed right flank pain and hydronephrosis. Creatinine remained at 0.9 mg/dL, but proteinuria measured by spot urine testing was at 1.9 g/g creatinine. CT and retrograde pyelogram demonstrated a unilateral ureteropelvic junction (UPJ) obstruction from suspected congenital stricture. The obstruction was corrected with a stent, followed by pyeloplasty. Intraoperative renal biopsy (at age 26 years) showed early reflex nephropathy, but no evidence of glomerulosclerosis on light microscopy or podocyte effacement on electron microscopy. Over the next few years, she developed progressive renal insufficiency with creatinine rising to 1.42 mg/dL, but proteinuria declined to 0.23 g/g creatinine.

Discussion

We described a patient with AMRF due to biallelic SCARB2 mutations with predicted loss of protein function. While these variants were previously identified in homozygous state in patients with AMRF, compound heterozygosity has not been described. The patient had prominent action myoclonus, controlled epilepsy, and dysphagia. Childhood-onset hearing loss in the maternal family was suspected to represent a separate entity of hereditary nonsyndromic deafness. Because SCARB2 mutations lead to GCase dysfunction and the patient was deteriorating rapidly, we assessed a trial of treatment with miglustat. Treatment resulted in arrest of progression of myoclonus, resolution of dysphagia, and mild overall sustained improvement over 3 years.

Treatment of AMRF with miglustat was described previously in 1 patient in 2011. In that report, 1 of the 2 siblings with AMRF (with homozygous SCARB2 variants introducing premature stop codon p.Trp178Ter) was treated with miglustat 600 mg/d for 2 years starting at age 24 years, after earlier GCase enzyme replacement therapy with no improvement for 1 year. The patient’s presentation, apart from the renal features, were similar to the patient we have presented, including an EEG showing generalized discharges, antiseizure medications yielding only transient benefit, instability due to myoclonic jerks, and requirement for nasogastric tube. Similar to our patient, myoclonus improved and dysphagia resolved; however, that patient died of pneumonia at age 26 years.

Myoclonus and seizures in AMRF progress independently of renal failure. Usually, renal manifestations include proteinuria, which may be nephrotic, with histology revealing

Figure 2 Clinical Course

The disease progressed over the first few years from bilateral tonic clonic seizures and falls to worsening action myoclonus and gait to bulbar symptoms. After the initiation of miglustat, starting at 200 mg/d and titrated up to 600 mg/d, disease progression halted, and the patient regained skills, including the ability to type and use a mobile phone. Each clinic or hospital visit is marked with a circle, with vertical position indicating whether the patient reported new/worsening symptoms (low), improving symptoms (high), or no change (middle).
interstitial fibrosis, atrophy, and focal segmental glomerulosclerosis (FSGS). However, some cases with certain biallelic SCARB2 variants have been described as not having progressive renal failure from FSGS. In our patient, kidney biopsy showed no evidence of FSGS (not repeated since). Subsequently, creatinine has progressively but slowly increased without concomitant rise in proteinuria, as is more typical of progressive renal failure from FSGS, including cases of FSGS in AMRF. It is unknown whether the renal phenotype was slowed by the miglustat treatment or whether her AMRF represents a variant SCARB2 mutation with milder kidney disease.

In addition, this patient had an anatomical UPJ obstruction, likely congenital, which was corrected surgically. She has not shown evidence of recurrent obstruction. However, the patient’s kidney biopsy indicated fibrosis in a striped pattern, which can be seen in obstructive nephropathy. Thus, her slowly progressive loss of kidney function may be more consistent with chronic obstructive nephropathy. UPJ obstruction has not been reported in patients with AMRF, including the previously reported patient who was treated with miglustat and had different renal pathology than our patient. It is, however, seen in Limp−/− mice, which develop hydronephrosis due to UPJ obstruction and proteinuria with glomerular foot-process effacement, but not FSGS.

The lysosomal pathway targeted in this case is important in other neurologic disorders. Human Parkinson disease (PD) brains have reduced GCase activity in substantia nigra. GBA mutations are a risk factor of PD, and genome-wide association studies suggest that SCARB2 variants may also increase PD risk. Miglustat is a weak GCS inhibitor; a higher potency alternative with better brain penetrance, venglustat, is now in trials for GBA mutation–associated PD and neuronopathic Gaucher disease.

Although this is a single case, it provides confirmation to a prior case report of miglustat responsiveness from 10 years ago, and because AMRF is relentlessly progressive with no other available therapies, consideration should be given to miglustat or related medications in patients with mutations in SCARB2 and conceivably other genes associated with impaired lysosomal metabolism. Our report is limited by subjectivity in reporting of myoclonus, dysphagia, and other symptoms. Future, larger, prospective trials should incorporate standardized scales for myoclonus and other symptoms. However, this therapy has the potential to be disease modifying, and we hope this report will encourage it to be tried early in the disease course as we gather additional evidence.

Acknowledgment
The authors thank the patient and her family for their participation as well as the Yale University DNA Diagnostics Laboratory.

Study Funding
The authors report no targeted funding.
